Abstract: Aldosterone is the main mineralocorticoid hormone controlling sodium balance, fluid homeostasis, and blood pressure by regulating sodium reabsorption in the aldosterone-sensitive distal nephron (ASDN). Germline loss-of-function mutations of the mineralocorticoid receptor (MR) in humans and in mice lead to the "renal" form of type 1 pseudohypoaldosteronism (PHA-1), a case of aldosterone resistance characterized by salt wasting, dehydration, failure to thrive, hyperkalemia, and metabolic acidosis. To investigate the importance of MR in adult epithelial cells, we generated nephron-specific MR knockout mice ($MR^{Pax8/LC1}$) using a doxycycline-inducible system. Under standard diet, $MR^{Pax8/LC1}$ mice exhibit inability to gain weight and significant weight loss compared to control mice. Interestingly, despite failure to thrive, $MR^{Pax8/LC1}$ mice survive but develop a severe PHA-1 phenotype with higher urinary Na^+ levels, decreased plasma $Na(+)$, hyperkalemia, and higher levels of plasma aldosterone. This phenotype further worsens on a deficient diet. Na^+/Cl^- co-transporter (NCC) protein expression and its phosphorylation are downregulated in the MR knockouts, as well as the ENaC protein expression level, whereas the expression of glucocorticoid receptor (GR) is increased. A diet rich in Na^+ and low in K^+ does not restore plasma aldosterone to control levels but is insufficient to restore ENaC protein expression independent of MR activity. Suppression of NCC under hyperkalemia predominates in a hypovolemic state.

Running head: MR required in adult kidney

Keywords: MR, GR, thiazide-sensitive Na⁺/Cl⁻ co-transporter, aldosterone, salt-losing syndrome

Abstract

Aldosterone is the main mineralocorticoid hormone controlling sodium balance, fluid homeostasis and blood pressure by regulating sodium reabsorption in the Aldosterone Sensitive Distal Nephron (ASDN). Germline loss-of-function mutations of the mineralocorticoid receptor (MR) in humans and in mice lead to the “renal” form of type 1 pseudohypoaldosteronism (PHA-1), a case of aldosterone resistance characterized by salt wasting, dehydration, failure to thrive, hyperkalemia and metabolic acidosis. To investigate the importance of MR in adult epithelial cells, we generated nephron-specific MR knockout mice ($MR^{Pax8/LC1}$) using a doxycycline inducible system. Under standard diet, $MR^{Pax8/LC1}$ mice exhibit inability to gain weight and significant weight loss compared to control mice. Interestingly, despite failure to thrive, $MR^{Pax8/LC1}$ mice survive but develop a severe PHA-1 phenotype with higher urinary Na^+ levels, decreased plasma Na^+ , hyperkalemia and higher levels of plasma aldosterone. This phenotype further worsens and becomes lethal under a sodium-deficient diet. NCC protein expression and its phosphorylated form are downregulated in the $MR^{Pax8/LC1}$ knockouts, as well as the $\alpha ENaC$ protein expression level, whereas the expression of glucocorticoid receptor (GR) is increased. A diet rich in Na^+ and low in K^+ does not restore plasma aldosterone to control levels, but is sufficient to restore body weight, plasma and urinary electrolytes. In conclusion, MR deletion along the nephron fully recapitulates the features of severe human PHA-1 and indicates that ENaC protein expression is dependent on MR expression and there are no compensatory mechanisms occurring. Hyperkalemia dominates the hypovolemic stimulus even at the expense of increased sodium loss.

Abbreviation list

ASDN: aldosterone sensitive distal nephron

MR: mineralocorticoid receptor

GR: glucocorticoid receptor

ENaC: epithelial sodium channel

NCC: Na⁺ / Cl⁻ co-transporter

AQP2: Aquaporin 2

Hsd11b2: 11 β -hydroxysteroid dehydrogenase type 2

PHA-1: type 1 pseudohypoaldosteronism

RAAS: Renin-Angiotensin-Aldosterone System

PCT: proximal convoluted tubule

PST: proximal straight tubule

TAL: thick ascending limb

DCT: distal convoluted tubule

CNT: connecting tubule

CCD: cortical collecting duct

Introduction

MR is expressed in Na⁺ transporting epithelia such as kidney and colon [11,21], but also in nonepithelial tissues (e.g. heart [20], vessels and brain [15,19,16]). Several inactivating autosomal dominant mutations of the MR gene (*NR3C2*) are the principal cause of renal and sporadic type 1 PHA which is a rare form of mineralocorticoid resistance characterized by neonatal renal salt wasting, failure to thrive, hyponatremia, hyperkalemia, and metabolic acidosis, accompanied by extremely high values of plasma renin and aldosterone levels. The severe and systemic form of PHA-1 is due to recessive mutations in the genes encoding for the three subunits of the epithelial sodium channel (ENaC) (MIM 600228; MIM 600760; MIM 600761). Germline MR-deficient mice present a normal prenatal development, but die within 8-12 days after birth from a salt-losing syndrome resembling the human PHA-1. They display hyponatremia, hyperkalemia, hypovolemia and activation of the Renin-Angiotensin-Aldosterone System (RAAS) with a strong increase in renin, angiotensin II, and aldosterone plasma concentrations. A strong reduction of the activity of ENaC in colon and kidney was also reported [5]. Interestingly, this phenotype can be rescued by subcutaneous injections of NaCl, although the animals retain their Na⁺-losing defect [7]. Inactivation of MR in the principal cells of the late connecting tubule (CNT) and of the collecting duct (CD) driven by the aquaporin 2 (AQP2) promoter can be compensated under a standard sodium diet, but not under a low-sodium diet [23]. This mild phenotype only partially recapitulates the severe human PHA-1 phenotype observed under standard salt diet and was explained by long term compensatory mechanisms [23]. The same authors used a tamoxifen-inducible strategy to delete MR partially within the CNT and cortical collecting ducts (CCD) during adulthood. Again, only under a low-salt diet and at adult stage, the induced ablation of MR recapitulates the renal sodium wasting observed in mice with constitutive early-onset MR ablation, but not hyperkalemia and/or increased mortality [24]. This was explained by compensatory mechanisms either by upregulation of sodium transporters upstream of the CNT i.e. the distal convoluted tubule 2 (DCT2) where ENaC and the Na⁺ / Cl⁻ co-transporter (NCC) are co-expressed [25], or by upregulation of ENaC-independent, non electrogenic sodium chloride transporters expressed along the CD [10]. To address this question, we developed an inducible renal tubule-specific MR knockout adult mouse model. Although MR^{Pax8/LC1} mice survive under a standard salt diet, they present with a severe renal PHA-1 phenotype characterized by increased weight loss, Na⁺ excretion, hyponatremia, hyperkalemia, high plasma aldosterone levels, and failure to thrive. Our data clearly show that MR expression along the nephron and

in the collecting duct system during adulthood is crucial for Na^+ and K^+ homeostasis, and its deletion cannot be compensated neither by sodium transporters including ENaC, nor by GR upregulation, but solely by a high Na^+ and low K^+ rescue diet.

Methods

Ethical approval

Animal maintenance and all experimental procedures in mice were in accordance with the Swiss federal guidelines and were approved by the veterinarian local authorities (“Service de la consommation et des affaires vétérinaires”) of the Canton de Vaud, Switzerland. Mice were kept in the animal facility under animal care regulations of the University of Lausanne. They were housed in groups of up to 5 in ventilated cages in a temperature- ($23\pm 1^{\circ}\text{C}$) and humidity-controlled room with an automatic 12-hour light/dark cycle. All animals had free access to laboratory chow and the water was supplied *ad libitum*. Data origin from both male and female animals. Experiments were performed in 3-week-old animals unless differently stated.

Generation of inducible renal tubule-specific MR^{Pax8/LC1} KO mice

Mice lacking MR all along the nephron and in the collecting duct system of the kidney were generated by using the Pax8-rtTA transgenic mouse line. Triple-transgenic conditional nephron-specific knockouts Nr3c2^{lox/lox};Pax8-rtTA^{tg/0};TRE-LC-1^{tg/0} (MR^{Pax8/LC1}) and control littermates Nr3c2^{lox/lox};Pax8-rtTA^{tg/0} (MR^{Pax8}), Nr3c2^{lox/lox};TRE-LC-1^{tg/0} (MR^{LC1}) and Nr3c2^{lox/lox} (MR^{lox}) were obtained by breeding Nr3c2^{lox/lox};Pax8-rtTA^{tg/0} mice with Nr3c2^{lox/lox};TRE-LC-1^{tg/0}. Nr3c2 deletion was induced in renal tubular cells upon doxycycline hydrochloride treatment (Sigma, Deisenhofen, Germany) (2 mg/ml and 2% sucrose in the drinking water) for 15 days in 4-week-old Nr3c2^{lox/lox};Pax8-rtTA^{tg/0};TRE-LC-1^{tg/0} knockout and Nr3c2^{lox/lox};Pax8-rtTA^{tg/0}, Nr3c2^{lox/lox};TRE-LC-1^{tg/0} and Nr3c2^{lox/lox} control mice.

Genotyping

DNA was recovered and extracted from mouse biopsies. Genotyping by PCR analysis was performed using the following primers: Pax8-rtTA: ST1 sense (5'-CCATGTCTAGACTGGACAAGA-3'); ST2 antisense (5'-CTCCAGGCCACATATGATTAG-3'); LC-1: Cre3 sense (5'-TCGCTGCATTACCGGTCGATGC-3'); Cre4 antisense (5'-CCATGAGTGAACGAACCTGGTCG-3'); Myogenin: 50S sense (5'-TTACGTCCATCGTGGACAGC-3'); 51S antisense (5'-TGGGCTGGGTGTTAGTCTTA-3'). Primers for myogenin served as a control for DNA integrity. The PCR program for Pax8-rtTA, LC-1 and Myogenin was the following: 37 cycles, each run consisted of 1 minute each

at 94°C, 56°C and 72°C. The knockout band corresponding to the recombination of the floxed Nr3c2 allele and thus MR deletion in the kidney was detected by PCR on whole kidney using the following primers: MR/Nr3c2: MRflox-1 sense (5'-CTCGAGATCTGAACTCCAGGCT-3'); MRflox-2 antisense (5'-CCTAGAGTTCCTGAGCTGCTGA-3'); MRflox-3 antisense (5'-TAGAAACACTTCGTAAAGTAGAGCT-3'). The PCR program for MR/Nr3c2 was the following: 35 cycles, each run consisted of 30 seconds at 95°C followed by 1 minute at 63°C and 1 minute at 72°C.

Quantitative RT-PCR on Kidney Samples

At the end of the experimentation mouse kidneys were isolated, frozen in liquid nitrogen and stored at -80°C. A Tissue-Lyser machine (Quiagen) was used to homogenize kidney's tissues. RNA was extracted from the lysed tissues using the guanidinium thiocyanate-phenol-chloroform extraction method (QIAzol lysis reagent, QUIAGEN) and its concentration and quality were measured and evaluated by the Nano Drop (Witec Ag ND-1000 Spectrophotometer). Then, the extracted RNA was used and cDNA was synthesized by retro-transcription using the PrimeScript RT reagent Kit (Takara Bio Inc, Japan). To quantify the relative mRNA expression of MR, 11 β -HSD2 and Ren-1 α , a Real-timePCR (Taq Man) was performed using Applied Biosystems 7500 (Foster City, CA). Primer and probe mixes (Mm01241592_mH for MR; Mm01251104_m1 for 11 β -HSD2; Mm02342887_mH for Ren-1 α ; 4352341E for β -Actin) and the Taqman Gene Expression Master Mix were purchased and used according to the manufacturer's instructions (Applied Biosystem, Foster City, CA). Each measurement was performed in duplicate. For each mRNA transcript detection and the control β -Actin, the cDNA, the primers and the probe were mixed and aliquoted together into the TaqMan Universal PCR Master mix (Applied Biosystem). Quantification of fluorescence was normalized to β -Actin fluorescence to quantify the relative mRNA transcripts expression in whole kidney.

Western Blot Analysis

Freshly isolated kidneys were homogenized by using the polytron. Homogenates were centrifuged for 10 minutes at 4°C at 11000 rpm. The supernatant was taken and protein concentration was measured by the Bradford method. Protein extracts from whole kidney were subjected to Western blot analysis. The proteins were loaded and separated on 10% polyacrylamide gels by SDS-PAGE, subjected to a constant electric current of 25 mA in running buffer 1x. Then the proteins were transferred onto a PVDF (Perkin Elmer, Boston,

MA) or nitrocellulose membrane (Amersham Hybond-ECL, GE Healthcare) applying a constant current of 100V during 3 hours in transfer buffer 1x. Membranes were subsequently investigated for Nr3c2 (MR), Scnn1a (α -ENaC), Slc12a3 (NCC) phosphorylated Slc12a3 (pT53-NCC), Nr3c1 (GR) and β -actin using primary antibodies Nr3c2 (1:100) [14], Scnn1a (1:500) [26], Slc12a3 (1:500) (Chemicon), pT53-Slc12a3 (1:1000; Pineda Antibody Services), Nr3c1 (1:1000; Santa Cruz, Dallas, TX) β -actin (1:1000; Sigma-Aldrich), anti-rabbit IgG secondary antibody (1:10000; Amersham, Buckinghamshire, UK) and anti-mouse IgG secondary antibody (1:10000; Jackson Immuno Research, Baltimore, PA). The secondary antibodies were coupled with horse Radish Peroxidase (GE Healthcare, millipore) that allows the revelation of the proteins by chemiluminescence with ECL reagents (GE Healthcare or Pierce, Rockford, IL). Thereby, the membranes were exposed on a photographic film (GE Healthcare, millipore) during different times in a cassette (Axon Lab) and developed. The films were scanned and the bands intensity was measured using Image Studio Lite Software from LI-COR Biosciences.

Immunofluorescence

Kidneys of anesthetized mice kept under regular salt diet were fixed with 3% paraformaldehyde and 0.1% glutaraldehyde in a cacodylate-sucrose buffer as described previously [18]. MR was detected by using a primary monoclonal antibody (mouse anti-rat-MR rMR1-18 [14], 1:40) incubated overnight at 4°C, and a secondary antibody goat-anti-mouse HRP (1:50, Jackson ImmunoResearch). The signal was amplified by using the Tyramide Signal Amplification (TSA) System (Perking Elmer). An antigen retrieval treatment was performed by microwave during 10 minutes at 98°C in 0.1 M citrate buffer (pH 6). Phosphorylated NCC was detected by using a rabbit-anti-mouse pT53NCC antibody [31] (1:40000) incubated overnight at 4°C, and a secondary antibody goat-anti-rabbit-CY3 (1:1000, Jackson ImmunoResearch). Staining was performed on 5 μ m sections.

Kidney perfusion and microdissection

Mice were anesthetized by a mixture of Ketamine/Xylazine/Acepromazine (100 mg/kg/ 15 mg/kg /2.5 mg/kg) injected intraperitoneally. The period of narcosis usually lasts 20-30 min. The perfusion is performed into the renal artery by using a catheter. Renal artery perfusion is made by 10 ml of DMEM F-12 (Dulbecco's Modified Eagle Medium: Nutrient Mixture F-12) followed by 10 ml Liberase (0.9 mg / ml, Liberase Blendzyme 4, Hoffmann-La Roche Inc.). Then, kidneys are microdissected as described previously [8]. 2 cm of each segment (PC, PS,

TAL, DCT/ CNT and CD) were recovered and processed for relative protein expression analysis. The microdissection was performed on 3 experimental and control animals.

Metabolic Cages Studies

Metabolic balance studies were performed to analyze the renal sodium, potassium and water homeostasis under normal sodium, sodium-deficient and high sodium and low potassium rescue diet. For time-course analyses, four- to six-week-old control and knockout mice from same litter were individually placed into mouse metabolic cages (Tecniplast, Buguggiate, Italy) and fed with different salt diets for 6 days. During the experimentation, body weight, urine volume, water and food consumption were determined and urine was collected every day at the same time. Experimental animals had free access to food and water during the experimentations in metabolic cages.

Regular sodium-diet

23 day-old control and KO mice were individually placed into metabolic cages. Mice were fed with a regular-salt diet (0.17% Na⁺ in the food, Ssniff Spezialdiäten GmbH) during the 6 days into the metabolic cages. Doxycycline treatment was started from day 2 (25 day-old) and applied till the end (day 6) of the metabolic cage study.

Sodium-deficient diet

25 day-old mice were placed in normal cages and treated with doxycycline for 15 days to induce MR-deficiency along the nephron and the collecting duct system. At the end of the doxycycline treatment control and KO mice were placed into metabolic cages and fed with a regular-salt diet (0.17% Na⁺ in the food, Ssniff Spezialdiäten GmbH) for 2 days, followed by 3 days of sodium-deficient diet (0.02% Na⁺ in the food, Ssniff Spezialdiäten GmbH).

High sodium and low potassium rescue diet

25 day-old mice were placed in normal cages and treated with doxycycline for 15 days to induce MR-deficiency along the nephron and the collecting duct system. During these 15 days of doxycycline treatment, mice were fed with a regular sodium diet (0.17% Na⁺ in the food, Ssniff Spezialdiäten GmbH) during the first week, and received a high sodium and low potassium rescue diet (3.5% Na⁺ in the food, Ssniff Spezialdiäten GmbH, and 0.2% K⁺ in drinking water) throughout the second week. At the end of the doxycycline treatment control and KO mice were placed into metabolic cages and continued to receive the rescue diet (high

Na⁺ and low K⁺) and had free access to tap water supplemented with 0.2% of potassium. At the end of experimentations, blood samples were collected and mice were sacrificed by decapitation. Freshly isolated kidneys were snap-frozen in liquid nitrogen and stored at -80°C for further molecular analysis.

Urine and Plasma analysis

Urine samples (12-24 hours) were collected in metabolic cages. At the end of experiments, blood samples were recovered. Urinary and plasma sodium and potassium concentrations were measured using the IL943 Flame Photometer (Instrumentation Laboratory, UK). Plasma aldosterone levels were measured according to standard procedure using the Coat-A-Count RIA kit (Siemens Medical Solutions Diagnostics, Ballerup, Denmark). Moreover, plasma corticosterone levels were quantified as previously described [30]. The urinary and plasmatic creatinine concentration measurements were performed by enzyme-linked immunosorbent assay (ELISA) at the Zurich Integrative Rodent Physiology platform (ZIRP, Zurich, Switzerland).

Determination of 11 β -HSD2 Enzyme Activity

11 β -HSD2 enzyme activity was measured as previously described [4].

Statistical Analysis

All measurements were analyzed using the unpaired two-tailed Student's t-test, considering MR^{Pax8/LC1} KO *versus* control mice, unless differently stated. Data are presented as mean \pm SEM. Values displaying a p-value smaller than 0.05 were considered as statistically significant. *P < 0.05, **P < 0.01, ***P < 0.001 and #P < 0.0001.

Results

Generation of inducible nephron-specific MR^{Pax8/LC1} knockout mice

We generated inducible renal tubule-specific MR knockout mice by using the *Nr3c2* floxed allele (*Nr3c2*^{lox/lox} [6]), the Pax8-rtTA transgenic mice expressing the reverse tetracycline transactivator under the control of the *Pax8* promoter that is driving the expression in all proximal and distal tubular cells along the nephron [32], and the LC1 transgenic mice where the expression of the Cre recombinase and luciferase is under the control of the tetracycline response element [28]. The reverse tetracycline transactivator binds and transactivates the tetracycline-responsive element in the presence of doxycycline, thereby triggering Cre recombinase expression and thus deletion of the floxed allele. We treated 4-week-old MR^{Pax8/LC1} triple transgenic animals (carrying the *Nr3c2*^{lox/lox}, Pax8-rtTA^{tg/0} and TRE-LC-1^{tg/0} transgenes and named MR^{Pax8/LC1}) and their control littermates (*Nr3c2*^{lox/lox}, Pax8-rtTA^{tg/0}, *Nr3c2*^{lox/lox}, TRE-LC-1^{tg/0}, and *Nr3c2*^{lox/lox} named MR^{Pax8}, MR^{LC1} and MR^{lox} respectively) with doxycycline to induce the deletion of the *Nr3c2* gene locus in adult mice. Quantitative mRNA expression measurement of MR revealed a 80% decrease in MR^{Pax8/LC1} knockout mice (Fig.1A), and Western blot analyses showed a 90% reduction of *Nr3c2* protein expression upon doxycycline treatment in the whole kidney (Fig.1B and C). Western blot analyses of microdissected nephron segments confirmed wild-type MR expression in the distal nephron, namely the thick ascending limb (TAL), distal convoluted tubule (DCT), connecting tubule (CNT), and in the cortical collecting ducts (CCD) in control mice, and demonstrated near-absence of MR protein expression in the corresponding segments of the MR^{Pax8/LC1} knockout mice (Fig.1D and Supplementary Fig. 1). The glucocorticoid receptor GR, the Na-K-Cl cotransporter NKCC2, the sodium-chloride symporter NCC, and the cytoplasmic Ca²⁺-binding protein calbindin CB28 were used as markers of the different nephron segments (Fig.1D). A strong reduction in MR expression in the MR^{Pax8/LC1} knockout mice could also be demonstrated by immunofluorescence (Fig. 1E). Pax8 expression has been described also in the liver [32], but we observed no changes of MR protein expression in this organ (Fig.1F and G).

Adult nephron-specific MR^{Pax8/LC1} knockout mice develop a PHA-1 phenotype under a regular sodium diet

We monitored the body weight of MR^{Pax8/LC1} knockout and control animals fed with a regular salt diet. MR^{Pax8/LC1} knockout mice rapidly stopped to gain body weight, whereas control

animals kept gaining weight (Fig. 2A) following the doxycycline induction. To determine urinary and plasma Na^+ and K^+ concentrations, we placed control and knockout animals into metabolic cages and performed measurements every 12 hours to evaluate the cyclicity of sodium, potassium and water excretion. $\text{MR}^{\text{Pax8/LC1}}$ knockout mice exhibited increased urine volume output and urinary Na^+ excretion under a standard salt diet (Fig. 2B and C), while the urinary K^+ excretion did not change (Fig. 2D). Interestingly, these differences are obvious only during the activity period (night) (Fig. 2B and D). The fractional excretion of K^+ did not vary between the two groups, while the fractional excretion of Na^+ was significantly increased in the knockouts (Fig. 2E and F) confirming that the increase in urinary sodium excretion reported in Figure 2C is not transient, but sustained upon regular sodium diet several weeks after MR deletion in renal tubules. $\text{MR}^{\text{Pax8/LC1}}$ knockout animals also presented with significantly lower natremia but still within the physiological range (135-145 mmol/l), and hyperkalemia (Fig. 3A, B). We observed no difference in food intake (Supplementary Table 1), and in plasma corticosterone levels (Fig. 3C). Urine creatinine concentration did not vary among the two groups (Supplementary Fig. 3A), however, plasma creatinine concentration was significantly higher (Supplementary Fig. 3B) and the creatinine clearance significantly reduced (Supplementary Fig. 3C) in the knockout animals indicating that kidney function is affected by the loss of MR in renal tubules. Moreover, plasma aldosterone levels markedly increased in the $\text{MR}^{\text{Pax8/LC1}}$ knockouts (Fig. 3D) mimicking a severe PHA-1 phenotype.

The PHA-1 phenotype becomes lethal under a sodium-deficient diet

The shift to a diet deficient in Na^+ caused a further decrease in the body weight of the knockout animals (Fig. 4A) leading to 100% death after three days of diet shift ($n=9$ $\text{MR}^{\text{Pax8/LC1}}$ knockouts). Water and food consumption did not change (Supplementary Table 1), however urine volume and urinary Na^+ excretion was increased and urinary K^+ excretion was significantly reduced in the $\text{MR}^{\text{Pax8/LC1}}$ knockout animals (Fig. 4B-D) that also presented with hyponatremia and hyperkalemia (Fig. 5A and B). Plasma corticosterone levels in the knockout animals increased following the shift from a regular Na^+ diet to a Na^+ -deficient diet (Fig. 5C). Plasma aldosterone further increased in the $\text{MR}^{\text{Pax8/LC1}}$ knockout mice under a sodium-deficient diet (Fig. 5D) to reach extraordinary high levels (40 nM) a concentration that should occupy 100% of MR and a significant proportion (about 20%) of GR [12].

High Na⁺ and low K⁺ diet restores body weight and electrolyte balance in MR^{Pax8/LC1} knockout mice

To counterbalance for Na⁺ loss and reduced K⁺ excretion, nephron-specific MR^{Pax8/LC1} knockout mice were subjected to a diet rich in Na⁺ and low in K⁺ during two weeks. Indeed, the knockout animals restored body weight gain compared to controls following high Na⁺ and low K⁺ treatment (Fig. 6A). Food and water intake (Supplementary Table 1), urinary and plasma Na⁺ and K⁺ concentrations and urine volume were indistinguishable between the two groups (Fig. 6B-D and Fig. 7A and B) but plasma aldosterone levels of MR^{Pax8/LC1} knockout animals remained significantly higher following high Na⁺ and low K⁺ diet (Fig. 7C). Thus, solely a diet rich in Na⁺ and low in K⁺ allows the MR^{Pax8/LC1} knockout mice to develop normally and to restore urine and plasma electrolytes.

Increased GR expression in the MR^{Pax8/LC1} knockout mice

Being both expressed in the ASDN, GR and MR have been proposed to have opposing effects, suggesting that activated GR can partially but not completely compensate for the loss of MR function [27,29,5,23]. We thus analysed GR protein expression in the kidney of MR^{Pax8/LC1} knockout mice by Western blot analyses. We found a moderate but significant increase in the protein expression of GR under normal Na⁺ diet (Fig. 8A and B). This increase was less obvious at the cellular level, as revealed by immunofluorescence analyses, and may be restricted to specific cell types (data not shown). Under Na⁺-deficient diet GR protein expression was about four-times significantly increased in the knockouts (Fig. 8C and D) indicating that MR deletion leads to increased renal expression of GR. This increase could be restored following the rescue (high Na⁺ / low K⁺) diet (Fig. 8E and F). Furthermore, mRNA levels of the 11 β -hydroxysteroid dehydrogenase (Hsd11b2) and renin (Ren-1^o) were significantly increased in the kidney of MR^{Pax8/LC1} knockout mice under both normal and Na⁺-deficient diets (Supplementary Fig. 2A-D), however the activity of the enzyme 11 β -hydroxysteroid dehydrogenase type 2 (Hsd11b2) did not vary (Supplementary Fig. 2E).

Decreased NCC activity in the MR^{Pax8;LC1} knockout mice despite severe salt-losing syndrome

To study whether the absence of MR in adult kidney might regulate the expression and function of sodium-transporting proteins, we analysed NCC and ENaC protein expression following induction of MR-deficiency under standard, Na⁺-deficient and rescue (high Na⁺ /

low K⁺) diets. MR^{Pax8/LC1} knockout mice presented with a significant decrease in the levels of total and phosphorylated NCC, and this decrease was even more pronounced under a Na⁺-deficient diet (Fig. 9A-D), but less important under the rescue diet (Fig. 9E and F). Immunofluorescence staining of perfused kidneys also revealed a decreased phospho-NCC expression in MR^{Pax8/LC1} knockout mice under a standard salt diet (Fig. 9G). The level of the α subunit of ENaC was also significantly reduced in the knockout animals (Fig. 9A-F). Altogether, these data indicate that the absence of MR in the nephron leads to NCC downregulation despite the increased sodium loss.

Discussion

We focused our study on the acute deletion of MR along the entire nephron and the collecting ducts of adult animals by using the Pax8-rtTA/LC-1 double transgenic mice [32]. MR^{Pax8/LC1} knockout mice present failure to thrive as a result of increased renal loss of sodium and water. The mutant mice also show highly increased plasma aldosterone levels on both standard and Na⁺-deficient diets developing a severe pseudohypoaldosteronism syndrome with rapid weight loss, disturbance of plasma Na⁺ and K⁺ concentrations, significantly increased urinary Na⁺ loss and decreased K⁺ excretion (Fig. 2-5). The phenotype observed in the MR^{Pax8/LC1} knockout mice is more severe than that observed in mice deficient for MR in renal principal cells in which inactivation of MR in CD and late CNT does not affect Na⁺ balance under standard conditions [23,24]. The results presented in this article clearly demonstrate that MR deficiency in the nephron during adulthood cannot be compensated by sodium transporting proteins upstream of late CNT (NCC [13]) or downstream along the CD (electroneutral sodium chloride reabsorption [10]), and that MR expression either in the TAL, DCT, or intercalated cells is crucial to maintain Na⁺ and K⁺ homeostasis.

Both MR and GR are expressed in the distal renal tubular cells [1] and can bind and be activated by the mineralocorticoid aldosterone and the glucocorticoid cortisol (corticosterone in mice and rats), respectively [17,12]. However, GR can also be bound and activated by aldosterone [12], which is a relatively weak GR agonist with a K_i of 140 nM [22]. Aldosterone stimulates also the transcriptional activity of GR at high concentrations [22]. Yet, in the MR^{Pax8/LC1} knockouts plasma aldosterone rises to a maximum of 40 nM (Fig. 3D and 5D). MR can also be bound and activated by cortisol (corticosterone in mice and rats), but since physiological glucocorticoids circulate in the blood at 100-1000 higher concentration than aldosterone, rapid conversion of cortisol to cortisone by the enzyme 11 β -hydroxysteroid dehydrogenase type 2 (11 β HSD2) allows aldosterone to selectively activate MR in epithelial tissues. *In vitro* and *in vivo* experimental models show that GR might play a role in renal sodium transport [3] being implicated in compensatory [5] or cooperative [12] mechanisms along with MR, and we thus hypothesized that GR in MR^{Pax8/LC1} knockout mice might compensate at least partially for the loss of MR. We found however no compensatory action of GR on MR in the context of renal salt transport, in spite of an overall increased GR protein expression in the kidney of the MR^{Pax8/LC1} knockout mice (Fig. 8A and B) that could not be confirmed by immunohistochemistry under a regular salt diet (data not shown) and the

increased plasma corticosterone levels of the knockouts following the shift to a Na⁺-deficient diet (Fig. 5C).

Sodium reabsorption in the aldosterone-responsive distal tubular segments is mediated by the amiloride-sensitive epithelial sodium channel ENaC expressed in the principal cells of the CD and CNT, together with the thiazide-sensitive sodium-chloride co-transporter NCC in the DCT [25]. Described as the “aldosterone paradox”, aldosterone can either trigger Na⁺ reabsorption in the DCT via the Na⁺/Cl⁻ co-transporter NCC and ENaC in DCT2, CNT and CD following a hypovolemic challenge, or increase NaCl delivery by inhibiting NCC activity in DCT responding to an hyperkalemic challenge. This results in differential regulation of Na⁺ and K⁺ transport between the DCT and the ASDN [2]. Aldosterone can activate ENaC through MR by inhibiting Nedd4-2 via phosphorylation by serum- and glucocorticoid-induced kinase 1 (Sgk1) [9], but aldosterone-activated MR can also bind to the promoter region of the gene encoding the α subunit of ENaC leading to *de novo* synthesis of this channel [33]. We found a reduction in the expression of the α ENaC protein in MR^{Pax8/LC1} deficient mice under normal, low-Na⁺ and high-Na⁺ / low-K⁺ rescue diets, showing that ENaC expression is under the control of MR (Fig. 9). As the knockout animals suffer from Na⁺ wasting, they could be in a hypovolemic state, and thus both hypovolemia and hyperkalemia may be present in the mutant animals. Aldosterone, which is highly increased in the knockouts, should activate NCC, but NCC is significantly less expressed and phosphorylated in the MR^{Pax8/LC1} mice (Fig. 9). This finding is surprising, as the MR^{Pax8/LC1} mice suffer from hyponatremia accompanied by high plasma aldosterone levels, and is consistent with the notion that the hyperkalaemic challenge dominates the hypovolemic stimulus in the context of the aldosterone paradox. We also found surprising no decreased K⁺ excretion under a standard diet (Fig. 2F) linked with hyperkalemia. This result was confirmed by three independent series of experiments (data not shown) and by measurements of urinary K⁺ fractional excretion (Fig. 2F). One possible explanation could be a reduced but still sufficient ENaC activity to allow normal urinary K⁺ excretion. However, this unchanged urinary K⁺ excretion in the MR^{Pax8/LC1} knockout mice is not sufficient to avoid the establishment of the hyperkalemic status.

Targeted inactivation of MR in the whole nephron and the collecting duct system with the exception of the glomeruli cannot be compensated on a standard diet by activation of the RAAS, which is reflected by upregulation of Ren-1^c expression in the kidney and the increased aldosterone levels in the blood of the MR^{Pax8/LC1} knockout mice (Suppl. Fig. 2 and Fig. 2 and 5). The decrease of NCC expression and phosphorylation (Fig. 9) might be induced

in an attempt to increase the Na^+ delivery to the CNT and CD where ENaC is normally highly expressed, allowing the exchange of Na^+ against K^+ . Thus, apical electrogenic ENaC-mediated transepithelial Na^+ reabsorption allows the excretion of K^+ from principal cells to the primary urine. However, inward Na^+ and outward K^+ transcellular fluxes are impaired in the $\text{MR}^{\text{Pax8/LC1}}$ knockout mice. Indeed, increased plasma aldosterone levels cannot activate MR in the $\text{MR}^{\text{Pax8/LC1}}$ knockouts, and thus aldosterone cannot trigger *de novo* synthesis of ENaC and ensure the channel stability at the apical membrane via the Sgk1 pathway.

In conclusion, the $\text{MR}^{\text{Pax8/LC1}}$ knockout mice fully reproduce the human PHA-1 phenotype, ENaC expression is dependent on MR activity and hyperkalemia is probably the main complication to be avoided even at the expense of increased Na^+ excretion.

Figure legends

Figure 1 Characterization of inducible renal tubule-specific MR^{Pax8/LC1} KO mice. (A) Quantification of *Nr3c2* mRNA expression relative to β -actin in whole kidney of MR^{Pax8/LC1} KO mice and their control littermates ($n = 4$ per genotype). (B) Analysis of MR protein expression by Western blot analysis in whole kidney lysates. β -actin was used as loading control ($n = 4$ per genotype). (C) Quantification of MR protein expression relative to β -actin of panel B. (D) Representative analysis of MR protein expression by Western blot analysis from microdissected renal tubules. PCT, proximal convoluted tubule; PST, proximal straight tubule; TAL, thick ascending limb; DCT, distal convoluted tubule; CNT, connecting tubule; CCD, cortical collecting duct. GR expressed throughout the whole nephron, NKCC2 as marker of the TAL, NCC solely expressed in the DCT and CNT, and CB28 as a distal marker of the nephron were used to define the different nephron segments. (E) Representative analysis of MR protein expression by immunofluorescence from total kidney under regular sodium diet ($n = 4$ per genotype). (F) Analysis of MR protein expression by Western blot analysis in whole liver lysates in KO ($n = 5$) and control mice ($n = 6$). (G) Quantification of MR protein expression in the liver relative to β -actin of panel E.

Figure 2 Weight loss, increased urine volume and urinary sodium excretion under regular sodium diet.

(A) Body weight of MR^{Pax8/LC1} KO and control mice before and following doxycycline treatment ($n = 7$ per genotype). (B, C and D) Time course for 12-h urine volume (B), urinary sodium excretion (C), urinary potassium excretion (D), fractional excretion (FE) of Na^+ ($n = 5-6$ per genotype) (E) and fractional excretion of K^+ ($n = 7$ per genotype) (F) determined in metabolic cages for MR^{Pax8/LC1} KO and control mice under regular sodium diet.

Figure 3 Decreased plasma sodium levels, hyperkalemia and increased plasma aldosterone levels under normal salt diet.

(A) Plasma sodium and (B) potassium concentrations in MR^{Pax8/LC1} KO ($n = 7$) and control ($n = 9$) mice following 4 days of doxycycline treatment. (C) Plasma corticosterone and (D) aldosterone levels measured in KO ($n = 8-11$) and control ($n = 8-11$) animals following 15 days and 4 days of doxycycline treatment, respectively. RS: regular sodium diet, 0.17% Na^+ in food.

Figure 4 Continuous body weight loss and decreased urinary potassium excretion upon sodium-deficient diet.

(A) Body weight under standard salt diet followed by a sodium-deficient diet. KO ($n = 9$) and controls ($n = 8$). (B, C and D) Time course for 12-h urine volume (B), urinary sodium excretion (C) and urinary potassium excretion (D) determined in metabolic cages in KO ($n = 9$) and control ($n = 8$) animals receiving a sodium-deficient diet.

Figure 5 Hyponatremia, hyperkalemia and highly increased plasma aldosterone levels under sodium-deficient diet.

(A) Plasma sodium and (B) potassium concentrations following 15 days of doxycycline treatment. KO ($n = 12$) and controls ($n = 15$). (C) Plasma corticosterone and (D) plasma aldosterone levels following 15 days of doxycycline treatment. ($n = 8-9$ per genotype). RS, regular sodium diet, 0.17% Na⁺ in food; SD, sodium-deficient diet, 0.02% Na⁺ in food. ** $P < 0.01$, KO under Na⁺-deficient versus KO under regular Na⁺ diet.

Figure 6 Restoration of body weight and urinary electrolytes upon high sodium and low potassium (rescue) diet.

(A) Body weight of MR^{Pax8/LC1} KO and control mice upon high sodium and low potassium diet ($n = 11$ per genotype). (B, C and D) Time course for 24-h urine volume (B), urinary sodium excretion (C) and urinary potassium excretion (D) determined in metabolic cages for MR^{Pax8/LC1} KO and control mice under a high sodium and low potassium diet ($n = 5$ per genotype).

Figure 7 Restoration of plasma electrolytes upon high sodium and low potassium (rescue) diet.

(A) Plasma sodium and (B) potassium concentrations in MR^{Pax8/LC1} KO ($n = 6$) and control ($n = 5$) mice under a high sodium and low potassium diet. (C) Plasma aldosterone levels measured in KO ($n = 6$) and control ($n = 5$) animals under a high sodium and low potassium diet. Measurements were performed following 15 days of doxycycline treatment and 15 days of rescue diet.

Figure 8 Increased GR protein levels upon regular and sodium-deficient diets. (A)

Representative Western blot analysis of GR and β -actin in whole kidney lysates under a regular sodium diet ($n = 6$ per genotype). (B) Graph shows quantification of Western blots for

GR from 2 independent experiments. (C) Representative Western blot analysis of GR and β -actin in whole kidney lysates under a sodium-deficient diet ($n = 6$ per genotype). (D) Graph shows quantification of Western blots in C. (E) Representative Western blot analysis of GR and β -actin in whole kidney lysates under a rescue (high Na^+ / low K^+) diet ($n \geq 5$ per genotype). (F) Graph shows quantification of Western blots in E.

Figure 9 Downregulation of NCC and α -ENaC protein expression.

(A) Representative Western blot analysis for total NCC, phosphorylated pT53-NCC and α -ENaC in kidney lysates from mice kept under regular sodium diet. β -actin was used as loading control ($n = 6$ per genotype). (B) Graphs show quantification of Western blots for NCC, pT53-NCC and α -ENaC from 2 independent experiments and normalized to β -actin ($n = 7$ per genotype). KO and control animals were kept upon regular sodium diet and proteins were extracted from the whole kidney. (C) Western blot analysis for total NCC, phosphorylated pT53-NCC and α -ENaC in kidney lysates from mice kept under sodium-deficient diet during three days. β -actin was used as loading control ($n = 4$ per genotype). (D) Graphs show quantification of Western blots for NCC, pT53-NCC and α -ENaC from 2 independent experiments and normalized to β -actin ($n = 7$ per genotype). KO and control animals were kept upon sodium-deficient diet and proteins were extracted from the whole kidney. (E) Western blot analysis for total NCC, phosphorylated pT53-NCC and α -ENaC in kidney lysates from mice kept under high Na^+ / low K^+ rescue diet. β -actin was used as loading control ($n \geq 5$ per genotype). (F) Graphs show quantification of Western blots in E. (G) Analysis of phospho-NCC protein expression by immunofluorescence from total kidney ($n = 4$ per genotype) upon regular sodium diet.

Acknowledgements

The authors would like to thank Günter Schütz and Stefan Berger for kindly providing us with the Nr3c2^{lox/lox} mouse line and Celso E. Gomez-Sanchez for the antibody against MR. We also like to thank Denise Kratschmar for LC-MS steroid measurements, and Anne-Marie Mérillat for figure editing. Moreover, the authors would like to thank all of the members of the laboratory of Edith Hummler for helpful and interactive discussions. Finally, the authors would like to acknowledge the contribution of the COST Action ADMIRE BM1301.
